Abstract

In order to explain and predict the behavior of agents, we use social cognition: we represent and reason about other's perspectives, knowledge, intentions, beliefs and 11 preferences. Traditional measures of social cognition (e.g., false belief change-of-location 12 tasks), however, often lack satisfactory psychometric properties: they are not designed to capture variation between children and rely on low trial numbers, dichotomous measures, and group averages. This has profound implications on what these studies can show. Poor 15 measurement of social cognition on an individual level may conceal relations between 16 different aspects of cognition and may obscure developmental change. To fully understand 17 how social-cognitive abilities emerge and relate to each other, we need new tools that can 18 reliably measure individual differences. To approach this issue, we designed a balloon 19 finding task to study social cognition in young children and adults. We concentrate on an essential ability that is involved in many social-cognitive reasoning processes: gaze cue 21 understanding – the ability to locate and use the attentional focus of an agent. Our 22 interactive web interface works across devices and enables supervised and unsupervised, as well as in-person and remote testing. The implemented spatial layout allows for discrete as well as continuous measures of participants' click imprecision and is easily adoptable to 25 different study needs. Here we show that our task induces inter-individual differences in a child (N = XXX) and adult (N = XXX) sample. Our two study versions and data 27 collection modes yield comparable results that show substantial developmental gains: the older children are, the more accurately they locate the target. High internal consistency and test-test reliability estimates underline that the capured variation is systematic. Furthermore, we find first evidence for the external validity of our task: the measured performance in gaze cue understanding relates to children's real life social surrounding. Taken together, this work shows a promising way forward in the study of individual differences in social cognition and will help us explore the in(ter)dependence of our core social-cognitive processes in greater detail.

Measuring individual differences in the understanding of gaze cues across the lifespan

39 Introduction

Developmental psychology is facing a dilemma: many research questions are
questions about individual differences, yet, there is a lack of tasks to reliably measure these
individual differences. Since children spend a large amount of their daily lives interacting
with and learning from others in social contexts, many studies investigate the emergence
and driving factors of social-cognitive abilities. Under social cognition, we understand the
ability to explain and predict the behavior of social agents by representing and reasoning
about their perspectives, knowledge, intentions, beliefs, and preferences.

Traditional tasks of social cognition (e.g., false belief change-of-location tasks)
frequently build upon dichotomous outcome variables (resulting in high chance levels),
small sample sizes and low numbers of trials per subject.

With these procedures, researchers could systematically track change on a group level and capture the average age at which children succeed in a given task that relies on a certain social-cognitive ability. However, poor psychometric properties may conceal relations between different aspects of cognition and also obscure developmental change.

If we want to answer questions about the co-development of social-cognitive abilities and the individual's pace of mastering developmental milestones, we need to take variation between children seriously – both methodologically and theoretically. We argue that a systematic individual differences perspective on social-cognitive development is needed.

To study individual differences, variability in task performance needs to be reliable (i.e., systematically order individuals in the same way) and meaningful (i.e., differences in test scores correspond to differences in ability).

A recent paper by Hedge, Powell, and Sumner (2018) argued that cognitive tasks often become well-established by displaying robust effects across studies. The authors

could show that this often does not emerge due to high measurement variance but rather
low between-subject variability, concluding that popular cognitive tasks may reliably
measure group differences but not individual differences. In a similar vein, Pronk,
Molenaar, Wiers, and Murre (2021) reasoned that accurate reliability estimates are needed
to judge how well a certain cognitive test is suited to draw inferences about individuals.

From previous studies that tried to relate several theoretically connected constructs to each other, we see mostly failed attempts. For example, Sodian et al. (2016) studied the relation between several social cognition measures. Against expectation, they could not find correlations between some theoretically connected constructs (e.g. implicit false belief and moral false belief understanding). Interestingly, nearly all measured variables were associated with their verbal IQ test. This shows that we are more likely to find associations between constructs when measures are actually designed to capture variation between individuals - similarly to how IQ tests are constructed. Therefore, it is conceivable that we are simply not able to capture existing underlying relationships with our existing tools - since they were mostly not created to quantify individual differences.

Our aim is, therefore, to make individual differences measurable in a systematic and reliable way. For getting precise person-specific estimates, we need an accurate measure of a child's given underlying social-cognitive ability. One of our main goals is to create a task that induces variation between children. To approach this issue, we focus on a continuous measure and short trials that facilitate more than a dozen replicates per subject.

To estimate the effect of inter-individual differences, we need a large sample size since since some of the effects that we are looking for might be small. Since data collection with families requires a lot of organizational effort, we want to enable data collection in-person with supervision as well as remotely without supervision. A standardized, easily accessible test procedure helps us to enable data collection at scale.

Another goal in creating new tasks should be to focus on the face value: we want to

- measure the underlying social-cognitive ability as straight-forward and directly as possible.
- ₉₀ Importantly, we can assess whether the task shows external validity by assessing the
- relationship with related constructs and factors of children's social surrounding.
- In our first novel task, we concentrated on the essential ability that is involved in many social-cognitive reasoning processes: gaze cue understanding - the ability to locate and use the attentional focus of an agent. The first component is often termed gaze following - turning ones eyes in the same direction as the gaze of another agent. By acting as a 'front end ability' (Brooks & Meltzoff, 2005, p. 535), following an agent's gaze provides insights into their intentions, thoughts, and feelings. In our definition, gaze cue understanding goes one step further by including the *acting* on the gaze-cued location.
- In many previous gaze following studies, the eye movement of an agent was
 accompanied by a congruent head movement thus, making it hard to disentangle which
 information the children rely on. In our task, we control the eye movement alone to
 pinpoint and break down children's abilities as detailed as possible.
- By implementing studies with open versus closed eyes conditions and head versus eye movement alone, researchers found that infants start gaze following in the narrow sense at the end of their first year of life (e.g., Brooks and Meltzoff (2005)). It is, however, unclear when and how children start to use these cues to guide their own active behavior.

Rakoczy, H. (2022). Foundations of theory of mind and its development in early childhood. Nature Reviews Psychology, 1–13. https://doi.org/10.1038/s44159-022-00037-z:

"ToM also has specific real-life consequences. First, the development of ToM 119 competence goes along with general measures of children's peer social skills in early and 120 middle childhood. (...) Second, ToM specifically predicts communicative competence. 121 (...) Third, ToM competence is related to the quality of peer relationships: children with 122 more advanced ToM are rated as more likeable and popular among their peers. Fourth, 123 children who are more proficient at ToM tasks tend to act more prosocially, including 124 comforting, sharing or helping other individuals. Finally, preschool ToM competence 125 predicts achievement in primary school, a relationship that is possibly mediated by social 126 competence, in that preschool ToM abilities enable subsequent social competence 127 development, which in turn contributes to school achievement." (p. 2) "Evidence for an 128 emerging understanding of perception at 9 months of age comes from various sources. For 120 example, children begin to follow the gaze of other agents in systematic and differential 130 ways: they follow an agent's head turn only when the agent can actually see (has their eyes 131 open rather than closed, or wears a transparent rather than an opaque blindfold)." (p. 2) 132 Developmental determinants: executive function, language ("that" complementations), 133 social (SES, siblings, mind-minded parents) Implicit tasks: "A third class of implicit ToM tasks is interaction tasks, in which participants are involved in a communicative or 135 cooperative interaction with another agent. This agent forms a mental state (such as a true 136 or false belief regarding the contents of a box) and experimenters measure whether 137 participants spontaneously take the agent's belief into account in their interaction with the 138 agent (for instance by helping or by interpreting the agent's communicative acts 139

accordingly)" (p. 9) => reliable & valid tasks to assess coherent development of
social-cognitive functions

Task design

43 Implementation

Our balloon finding task is presented as an interactive web app. The task is portable across devices and web browsers and does not require any installation. An advantage of online testing is that our testing procedure is standardized across participants. By using pre-recorded study instructions, no interaction with the experimenter is necessary during the study. The code is open-source (https://github.com/ccp-eva/gafo-demo) and a live demo version can be found under: https://ccp-odc.eva.mpg.de/gafo-demo/.

The web app was programmed in JavaScript, HTML5, CSS and PHP. For stimulus 150 presentation, a scalable vector graphic (SVG) composition was parsed. This way, the 151 composition scales according to the user's view port without loss of quality, while keeping 152 the aspect ratio and relative object positions constant. Furthermore, SVGs allow us to 153 define all composite parts of the scene (e.g., pupil of the agent) individually. This is needed 154 for precisely calculating exact pupil and target locations and sizes. Additionally, it makes it 155 easy to adjust the stimuli and, for example, add another agent to the scene. The web app 156 generates two file types: (1) a text file (.json) containing meta-data, trial specifications and 157 participants' click responses, and (2) a video file (.webm) of the participant's webcam 158 recording. These files can either be sent to a server or downloaded to the local device. 150

60 Stimuli

Our newly implemented task features an online game where children or adults are
asked to search for a balloon. The events proceed as follows (see Figure 1B and C). An
animated agent (a sheep, monkey, or pig) looks out of a window of a house. A balloon (i.e.,

target; blue, green, yellow, or red) is located in front of them. The target then falls to the 164 ground. At all times, the agent's gaze tracks the movement of the target. That is, the 165 pupils and iris of the agent move in a way that their center aligns with the center of the 166 target. While the distance of the target's flight depends on the final location, the target 167 moves at a constant speed. Participants are then asked to locate the target: they respond 168 by touching or clicking on the screen. Visual access to the target's true location is 169 manipulated by a hedge. Participants either have full, partial, or no visual access to the 170 true target location. When partial or no information about the target location is accessible, 171 participants are expected to use the agent's gaze as a cue. 172

To keep participants engaged and interested, the presentation of events is 173 accompanied by cartoon-like effects. Each trial starts with an attention-getter: an 174 eye-blinking sound plays while the pupils and iris of the agent enlarge (increase to 130%) 175 and change in opacity (decrease to 75%) for 0.3 sec. The landing of the target is 176 accompanied by a tapping sound. Once the target landed, the instructor's voice asks 177 "Where is the balloon?". For confirming the participant's click, a short plop sound plays 178 and a small orange circle appears at the location of choice. If no response is registered 179 within 5 secs after the target landed, an audio prompt reminds the participant to respond. 180

181 Trials

Trials differ in the amount of visual access that participants have to the final target position. Before the test trials start, participants complete four training trials during which they familiarize themselves with clicking the screen. In the first training trial, participants have full visual access to the target flight and the target's end location and are simply asked to click on the visible balloon. In the second and third training trials, participants have partial access: they witness the target flight but cannot see the target's end location. They are then asked to click on the hidden balloon, i.e., the location where they saw the target land. In test trials, participants have no visual access to the target flight or the end

location. Participants are expected to use the agent's gaze as a cue to locate the target.

The first trial of each type comprises a voice-over description of the presented events. The

audio descriptions explicitly state that the agent is always looking at the target (see

Appendix for audio script). After the four training trials, participants receive 15 test trials.

The complete sequence of four training trials and 15 test trials can be easily completed

within 5-10 minutes.

196 Study versions

We designed two study versions which differ in the final hiding place of the target 197 and, consequently, on the outcome measure: a hedge version (continuous) and a box version 198 (discrete). Both versions use the same first training trial and then differ in the consecutive 199 training and test trials. In the hedge version, participants have to indicate their estimated 200 target location directly on a hedge. Here, the dependent variable is imprecision, which is 201 defined as the absolute difference between the target center and the x coordinate of the 202 participant's click. In the box version, the target lands in a box and participants are asked 203 to click on the box that hides the target. Researchers have the choice how many boxes are 204 shown: one up to eight boxes can be displayed as potential hiding locations. Here, we use a categorical outcome (i.e., which box was clicked) to calculate the proportion of correct responses. Note that in the test trials of both versions, the target flight is covered by a 207 hedge. In the hedge version, the hedge then shrinks to a minimum height required to cover 208 the target's end location. In the box version, the hedge shrinks completely. The boxes then 200 hide the target's final destination (see Figure 1B and C).

211 Randomization

All agents and target colors appear equally often and are not repeated in more than two consecutive trials. The randomization of the target end location depends on the study version. In the hedge version, the full width of the screen is divided into ten bins. Exact

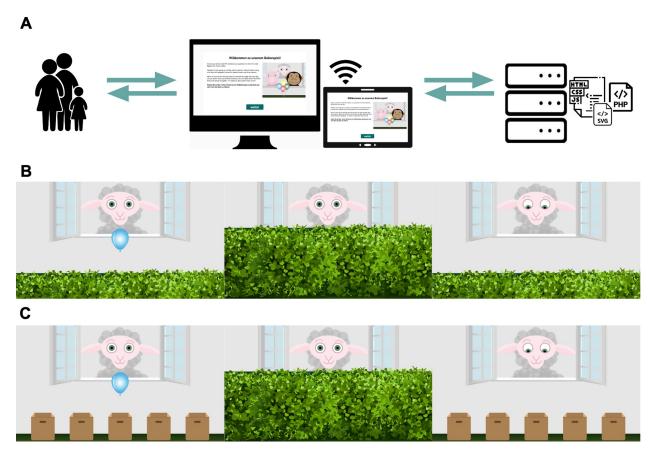

Figure 1. Study setup. (A) Infrastructure for online testing. (i) Subjects aged 3 – 99+ can participate. Data collection can take place anywhere: online, in kindergartens or research labs. (ii) The task is presented as a website that works across devices. (iii) The scripts for the website and the recorded data are stored on secure local servers. (B) Hedge version (continuous) of the balloon finding task. (i) The agent stands in a window with the target in front of them. (ii) A hedge grows and covers the target. (iii) The target falls to a random location on the ground. The agent's eyes track the movement of the target. (C) Box version (discrete) of the balloon finding task. Number of boxes (min. 1; max. 8) as potential hiding locations can be set according to the researcher's need.

coordinates within each bin are then randomly generated. In the box version, the target randomly lands in one of the boxes. As with agent and color choice, each bin/box occurs equally often and can only occur twice in a row.

Individual differences

Our first aim was to assess whether our balloon finding task induces inter-individual variation in a child and adult sample. Furthermore, we were interested in how the data collection mode influences responses.

Methods, sample size and analysis were pre-registered: https://osf.io/snju6 (child sample) and https://osf.io/r3bhn (adult sample). Participants were equally distributed across the two study versions. The study was approved by an internal ethics committee at the Max Planck Institute for Evolutionary Anthropology. Data was collected between May and October 2021.

227 Participants

228

238

218

remote adult sample. In-person testing with children took place in kindergartens in 220 Leipzig, Germany. The in-person child sample consisted of 120 children, including 40 230 3-year-olds (mean = 41.45 months, SD = 3.85, range = 36 - 47, 22 girls), 40 4-year-olds 231 (mean = 54.60 months, SD = 3.10, range = 48 - 59, 19 girls), and 40 5-year-olds (mean = 54.60 months)232 66.95 months, SD = 3.39, range = 60 - 71, 22 girls). 233 For our remote child sample, we recruited families via an internal database. The 234 remote child sample included 147 children, including 45 3-year-olds (mean = 42.62 months, 235 SD = 3.35, range = 36 - 47, 14 girls), 47 4-year-olds (mean = 52.64 months, SD = 3.40, 236 range = 48 - 59, 25 girls), and 55 5-year-olds (mean = 65.11 months, SD = 3.77, range = 237

60 - 71, 27 girls). Children in our sample grow up in an industrialized, urban

We collected data from an in-person child sample, a remote child sample, and a

Central-European context. Information on socioeconomic status was not formally recorded,
although the majority of families come from mixed, mainly mid to high socioeconomic
backgrounds with high levels of parental education.

Adults were recruited via *Prolific*. *Prolific* is an online participant recruitment service from the University of Oxford with a predominantly European and US-american subject pool. Participants consisted of 50 and 50 English-speakers with an average age of 31.92 and 30.76 years (SD = 12.15 and 9.12, range = 18 and 19 - 63 and 59, 36 and 28 females). For completing the study, subjects were payed above the fixed minimum wage (in average £10.00 per hour).

248 Procedure

Children in our in-person sample were tested on a tablet in a quiet room in their 249 kindergarten. An experimenter guided the child through the study. Children in the remote 250 sample received a personalized link to the study website and families could participate at 251 any time or location they wanted. In the beginning of the online study, families were 252 invited to enter our "virtual institute" and were welcomed by an introductory video of the 253 study leader, shortly describing the research background and further procedure. Then, 254 caregivers were informed about data security and were asked for their informed consent. 255 They were asked to enable the sound and seat their child centrally in front of their device. 256 Before the study started, families were instructed how to setup their webcam and enable 257 the recording permissions. We stressed that caregivers should not help their children. 258 Study participation was video recorded whenever possible in order to ensure that the answers were generated by the children themselves. Depending on the participant's device, the website automatically presented the hedge or box version of the study. For families that used a tablet with touchscreen, the hedge version was shown. Here, children could directly 262 click on the touchscreen themselves to indicate where the target is. For families that used a 263 computer without touchscreen, the website presented the box version of the task. We 264

assumed that younger children in our sample would not be acquainted with the usage of a computer mouse. Therefore, we asked children to point to the screen, while caregivers were asked to act as the "digital finger" of their children and click on the indicated box.

All participants received 15 test trials. In the box version, we decided to adjust the task difficulty according to the sample: children were presented with five boxes while adults were presented with eight boxes as possible target locations.

271 Analysis

All test trials without voice over description were included in our analyses. We ran all analyses in R version 4.2.0 (2022-04-22) (R Core Team, 2022). Regression models were fit as Bayesian generalized linear mixed models (GLMMs) with default priors for all analyses, using the function brm from the package brms (Bürkner, 2017, 2018).

To estimate the developmental trajectory of gaze cue understanding and the effect of 276 data collection mode, we fit a GLMM predicting the task performance by age (in months, 277 z-transformed) and data collection mode (reference category: in-person supervised). The 278 model included random intercepts for each participant and each target position, and a random slope for symmetric target position within participants (model notation in R: 280 performance ~ age + datacollection + (symmetricPosition | subjID) + (1 | 281 targetPosition)). Here, targetPosition refers to the exact bin/box of the target, while 282 symmetricPosition refers to the absolute distance from the stimulus center (i.e., smaller 283 value meaning more central target position). We expected that trials could differ in their difficulty depending on the target centrality and that these these item effects could vary 285 between participants. 286

For the hedge version, performance was defined as the absolute click distance between
the target center and the click X coordinate, scaled according to target widths, and
modeled by a lognormal distribution. For the box version, the model predicted correct

responses (0/1) using a Bernoulli distribution with a logit link function. We inspected
the posterior distribution (mean and 95% Confidence Interval (CI)) for the age and data
collection estimates.

$_{^{293}}$ Results

310

311

We found a strong developmental effect: with increasing age, participants got more 294 and more accurate in locating the target. In the hedge version, children's click imprecision 295 decreased with age, while, in the box version the proportion of correct responses increased (see Figure 2A and F). Most participants in the box version performed above chance level. By the end of their sixth year of life, children came close to the adult's proficiency level. 298 Most importantly, however, we found substantial inter-individual variation across study 299 versions and age groups. For example, some three-year-olds were more precise in their 300 responses than some five-year-olds. Even though variation is smaller, we even find 301 inter-individual differences in the adult sample. 302

As Figure 2A and F show, our remotely collected child data resembled the data from
the kindergarten sample. We found evidence that responses of children participating
remotely were slightly more precise. This difference was mainly driven by the younger
participants and especially prominent in the box version of the task. It is conceivable that
caregivers were especially prone to influence the behavior of younger children. In the box
version, caregivers might have had more opportunities to interfere since they carried out
the clicking for their children.¹

Our GLMM analysis corroborated the visual inspection of the data: in the hedge version, the estimates for age ($\beta = -0.32$; 95% CI [-0.41; -0.24]) and data collection mode

 $^{^1}$ In an exploratory analysis, we coded parental behavior and environmental factors during remote unsupervised testing. We focused on the subsample with the greatest performance difference between data collection modes: the three-year-olds in the box version of the task (n = 16). We reasoned that if parental interference cannot explain the greatest performance difference in our sample, the effects would be negligible in the remaining sample. Based on our model comparison, we conclude that there is no clear evidence of a stable effect of parental interference. See Supplements for further detail.

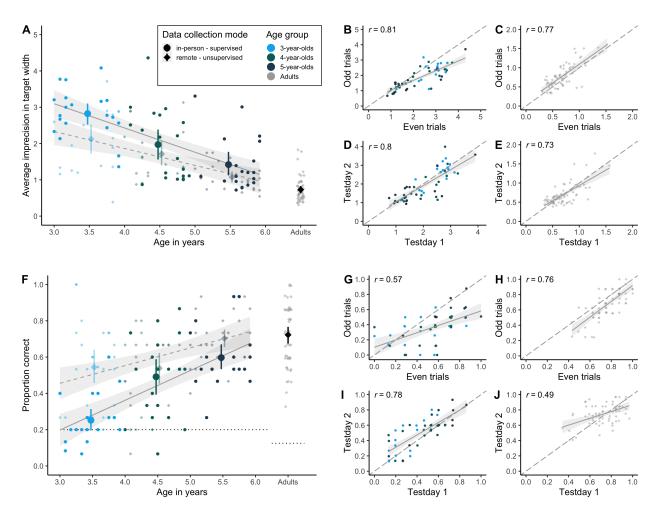

Figure 2. Measuring inter-individual variation. (A) Developmental trajectory in continuous hedge version. Performance is measured as average imprecision, i.e., the absolute distance between the target's center and the participant's click. The unit of imprecision is counted in the width of the target, i.e., a participant with an imprecision of 1 clicked in average one target width to the left or right of the true target center. (B) Internal consistency (odd-even split) in hedge child sample. (C) Internal consistency in hedge adult sample. (D) Test-retest reliability in hedge child sample. (E) Test-retest reliability in hedge adult sample. (F) Developmental trajectory in discrete box version. Performance is measured as the proportion of correct responses, i.e., how many times the participant clicked on the box that actually contained the target. Dotted black line shows level of performance expected by chance (for child sample 20%, i.e., 1 out of 5 boxes; for adult sample 12.5%, i.e., 1 out of 8 boxes). (G) Internal consistency (odd-even split) in box child sample. (H) Internal consistency in box adult sample. (I) Test-retest reliability in box child sample. (J) Testretest reliability in box adult sample. Regression lines with 95% CI show smooth conditional mean based on a linear model (generalized linear model for box version), with *Pearson*'s correlation coefficient r. Large points with 95% CI (based on non-parametric bootstrap) represent performance means by age group (binned by year). Small points show the mean performance for each subject. Shape of data points represents data collection mode: opaque circles for in-person supervised data collection, translucent diamonds for remote unsupervised data collection. Color of data points denotes age group.

only -0.32 (95% CI [-0.49; -0.14]) were negative and reliably different from zero. In the box version, the estimate of age (β =0.63 (95% CI [0.40; 0.88]) and the estimate of data collection mode (β = 1.12 (95% CI [0.69; 1.57]) were positive and reliably different from zero. Note that even though confidence intervals from the data collection estimates were wide, the effect was positive and reliably different from zero in a way that our remote sample performed more accurately than our in-person sample.

Discussion

326

Our task induced inter-individual variation in both adults and children. We see
substantial developmental gains: with increasing age, participants got more and more
precise in locating the target. The five-year-olds reached a proficiency level close to the
adults' level. For neither study version nor age group did we find any floor or ceiling
effects. The presentation as a tablet game kept children interest and motivated throughout
the 15 test trials. Furthermore, we found a comparable developmental trajectory for an
unsupervised remote child sample. This illustrates the flexibility of the task.

Internal consistency and retest reliability

As a next step, we aimed at investigating whether the variation that we captured
with our balloon finding task is reliable. We assessed internal consistency (split-half
reliability) and test-retest reliability. Data collection and analysis were pre-registered (can
be found here: https://osf.io/xqm73 for child sample, and https://osf.io/nu62m adult
sample). Participants were equally distributed across the two study versions. The study
was approved by an internal ethics committee at the Max Planck Institute for Evolutionary
Anthropology. Data was collected between July 2021 and April 2022.

Participants

Participants were recruited in the same way as in the previous study. The child sample consisted of 106 children, including 35 3-year-olds (mean = 42.57 months, SD = 2.98, range = 38 - 47, 17 girls), 38 4-year-olds (mean = 53.77 months, SD = 3.16, range = 48 - 59, 20 girls), and 33 5-year-olds (mean = 66.12 months, SD = 3.36, range = 61 - 71, 17 girls).

The adult sample consisted of 70 and 66 English-speakers with an average age of 25.43 and 26.05 years (SD = 6.43 and 9.44, range = 18 and 18 - 51 and 71, 45 and 42 females).

Procedure Procedure

We applied the same procedure as in the first study, with the following differences. 343 Participants completed the study twice, with a delay of 14 ± 3 days. The target locations as well as the succession of agents and target colors was randomized once and then held constant across participants. The child sample received 15 test trials. In the hedge version, each bin occurred once, making up ten of the test trials. For the remaining five test trials, 347 we repeated one out of two adjacent bins (i.e., randomly chose between bin 1 & 2, bin 3 & 4, etc). In the box version, we ensured that each of the five boxes occurred exactly three 349 times. For the remaining training trials, we repeated a fixed order of four random 350 bins/boxes. Adults in the hedge version received 30 test trials, each of the ten bin 351 occurring exactly three times. Adults in the box version received 32 test trials with each of 352 the eight boxes occurring exactly four times. 353

354 Analysis

We assessed reliability in two ways. First, we focused on the internal consistency by
calculating splithalf reliability coefficients. For each subject, trials were split into odd and
even trials, performance was aggregated and then correlated using *Pearson* coefficients. For

this, we used the data of the first test day. Performance was defined according to study 358 version: in the hedge version, performance referred to the mean absolute difference between 359 the target center and the click coordinate, scaled according to target widths; in the box 360 version, we computed the mean proportion of correct choices. Pronk et al. (2021) recently 361 compared various methods for computing split-half reliability that differ in how the trials 362 are split into parts and whether they are combined with stratification by task design. To 363 compare our traditional approach of a simple odd-even split, we additionally calculated 364 reliability estimates using first-second, odd-even, permutated, and Monte Carlo splits 365 without and with stratification by target position. First-second and odd-even splits belong 366 to single sample methods, since each participant has a single pair of performance scores, 367 while permutated (without replacement) and Monte Carlo (with replacement) splits make 368 use of resampling. Analyses were run using the function by split from the splithalfr package (Pronk et al., 2021). 370

Second, we assessed the test-retest reliability. We calculated performance scores 371 (depending on study version as described above) for each participant in each test session 372 and correlated them using Pearson correlation coefficients. Furthermore, for our child 373 sample we report an age-corrected correlation between the two test days using a GLMM 374 based approach (Rouder & Haaf, 2019). We fit trial by trial data with a fixed effect of age, 375 a random intercept for each subject and a random slope for test day (model notation in R: 376 performance ~ age (0 + reliday | subjID)). For the hedge version, performance was 377 modeled by a lognormal distribution, while the model for the box version used a Bernoulli 378 distribution with a logit link function. The model computes a correlation between the participant specific estimates for each test day. This can be interpreted as the test-retest reliability. By using this approach, we do not need to compromise on data aggregation and, therefore, loss of information. Since the model uses hierarchical shrinkage, we obtain 382 regularized, more accurate person-specific estimates. Most importantly, the model includes 383 age as a fixed effect. The correlation between the two person-specific estimates is 384

consequently the age-independent estimate for test-retest reliability. This rules out the
possibility that a high correlation between test days arises from domain general cognitive
development instead of study-specific inter-individual differences. A high correlation
between our participant specific model estimates would speak for a high association
between test days.

Results

We found that our balloon finding task induced systematic variation: splithalf and 391 test-retest reliability was high for most samples. For the internal consistency, we show 392 traditional odd-even splits on our data and the corresponding *Pearson* correlation coefficients in Figure 2B, C, G and H. Figure 3 compares splithalf reliability coefficients by splitting and stratification method (Pronk et al., 2021). In the hedge version, the splithalf reliability coefficients ranged from 0.57 to 0.84. In the box version, splithalf reliability coefficients ranged from 0.49 to 0.76. Similarly to the results of Pronk et al. (2021), we found that more robust splitting methods that are less prone to task design or time 398 confounds yielded higher reliability coefficients. In the majority of cases, stratifying by 399 target position lead to similar or even higher estimates compared to no stratification. As 400 might be expected, we found higher coefficients for the samples with higher variation, i.e., 401 for our continuous hedge version of the task. 402

For the test-retest reliability, we show the association between raw performance scores of the two test days and corresponding *Pearson* correlation coefficients in Figure 2D, E, I and J.²

The age-corrected, GLMM based retest reliabilities for children yielded similar results. In hedge version it was 0.90 (95% CI [0.68;1.00]). In the box version it was 0.92

² In the hedge version, we excluded one 5-year-old child from the test-retest analysis. The performance of the mentioned child was 3 standard deviations above the mean on both test days. Including the child yielded a *Pearson* correlation coefficient of r = 0.87.

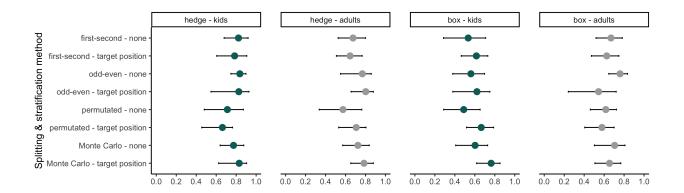

Figure 3. Internal Consistency. Reliability coefficients per splitting method, stratification level, study version and age group. Error bars show the 95% confidence intervals of the coefficient estimates, calculated with the function by_split from the splithalfr package (Pronk et al., 2021).

408 (95% CI [0.70;1.00]).

Discussion

418

419

420

421

Our results indicated that the measured variation was systematic. As could be
expected, the continuous measure of the hedge version yielded higher reliability estimates
than the discrete box version. For children, the model based reliability estimates showed
that the task did capture individual differences even when correcting for age. This
corroborates what we already see in Figure 2: there was a clear overlap between age
groups, indicating that age is predictive of performance for the mean, but is not the main
source of individual differences.

Validity Validity

Our third aim was to assess whether the captured individual variation in gaze cue understanding relates to factors in children's real live social environment [m: kurz sagen warum wir das erwarten - also dass frühere studien hier links sehen (zitieren) und die mit anderen measures of social cognition auch finden. Daher sehen wir das als indikator für validität, wenn wir das auch finden.]

Participants

For this exploratory analysis, we included all children of the aforementioned samples where families filled out a short demographic questionnaire. This subsample consisted of 137 children, including 42 3-year-olds (mean = 43.04 months, SD = 3.25, range = 36 - 47, 23 girls), 46 4-year-olds (mean = 54.43 months, SD = 2.76, range = 48 - 59, 34 girls), and 49 5-year-olds (mean = 66.25 months, SD = 3.47, range = 60 - 71, 27 girls).

429 Procedure

Families of our kindergarten and online child sample were asked to fill out a brief
demographic questionnaire. We asked for (1) the total number of household members, (2)
the number of children, (3) age of the other children, (4) whether the child was in day care,
and if yes, (5) since when and (6) for how long on an average day.

434 Analysis

To estimate the effects of social surrounding on gaze cue understanding, we fit 435 GLMMs predicting the task performance by each of our questionnaire variables, controlling 436 for age (in months, z-transformed), data collection mode (reference category: in-person 437 supervised) and study version (reference category: hedge version). The models included 438 random intercepts for each participant and each target position, and a random slope for 439 symmetric target position within participants. Therefore, our null model closely resembled 440 the structure from our first analysis (see Analysis section of Does the balloon finding task induce variation?; here: performance ~ age + datacollection + studyversion + (symmetricPosition | subjID) + (1 | targetPosition)). In order to combine data of our two study versions, we transformed continuous click responses from the hedge version into a discrete outcome. For the target position, we categorized two adjacent bins as one 445 imaginary box. To measure participants' performance, we created imaginary box

boundaries around the target's landing position and examined whether the participant's click response fell into this imaginary box. Across the two study versions, we could 448 consequently model the participant's correct response (0/1) using a Bernoulli distribution 449 with a logit link function. For model comparisons, we ran separate models, each with one 450 of the following predictors as a fixed effects added to the null model: number of household 451 members, number of children aged 0-18 in household, number of children aged 1-12 in 452 household, hours spent in childcare each day, and age when subject entered childcare. In 453 addition, we calculated three index scores. First, we calculated a sibling variety score 454 according to Peterson (2000). Second, we implemented the modified version of Cassidy, 455 Fineberg, Brown, and Perkins (2005) (for more details, see Supplements). Third, based on 456 our own data exploration, we calculated the amount of peer exposure determined as the 457 number of siblings and the average hours spent in childcare (both z-transformed). We compared the models using WAIC (widely applicable information criterion) scores and weights (McElreath, 2020). As an indicator of out-of-sample predictive accuracy, lower WAIC scores stand for a better model fit. WAIC weights represent the probability that the 461 model in question provides the best out-of-sample prediction compared to the other models. 462

463 Results

The model including our peer exposure index, as defined as the number of other children in the household and average hours spent in childcare, showed the best out-of-sample predictive accuracy. Note that we did not find a great difference in WAIC scores between the compared models (see Supplements for WAIC scores and weights). The model estimates were all considerably smaller than estimates of age, study version and data collection, and all 95% CIs included zero. For example, for our winning model, we found a peer exposure estimate of $\beta = 0.17$ (95% CI [-0.03; 0.36]), with the estimates of age being $\beta = 0.57$ (95% CI [0.38; 0.77]), data collection mode being $\beta = 0.95$ (95% CI [0.56; 1.35]), and study version $\beta = 1.87$ (95% CI [0.25; 3.59]). Nevertheless, a general pattern

emerges: exposure to a more variable social environment positively influenced children's
gaze cue understanding. The number of people and, more specifically, children, as well as
the more diverse their age, the more likely children were to understand the agent's gaze
cue. The only predictor resulting in a negative estimate was the age at which a participant
entered childcare, i.e., the later a child entered, the better performance in the task.

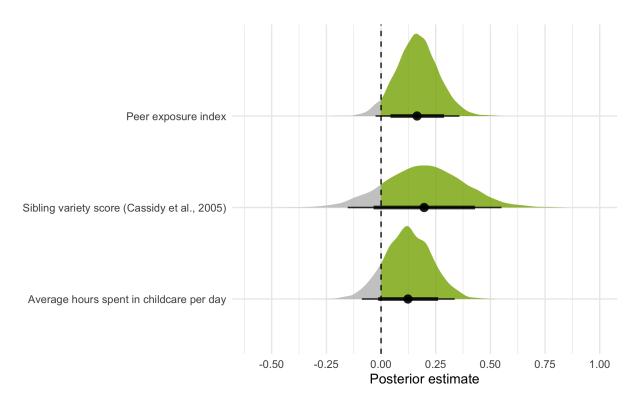

Figure 4. External validity of the balloon finding task. Factors of children's social surroundings and their influence on the probability of responding correctly. Models are ordered according to their WAIC scores, with the uppermost winning the model comparison. The graph shows the estimated density curves of a model's predictor coefficient. Only models performing better than our null model are included in the graph.

478 Discussion

In line with previous research, We found that factors of children's social surrounding influenced their gaze cue understanding. Even though the effects are small and confidence intervals wide, it is remarkable that we were able to detect relationships between this fundamental social-cognitive ability and very distant, real life variables [m: das ein

bisschen aufdröseln - also sagen dass frühere tassk sich komplexere sahcen angeguckt haben und wir aber schon sehen, dass es schienbar systeamtische sachen gibt bei den einfachen dingen die wir hier messen].

486 Discussion

We were able to show that our balloon finding task measures inter-individual
variation between children and adults, alike. Our results suggest that the measured
variation is systematic during the course of the same and different test days. Impressively,
gaze cue understanding as measured by our task related to factors in children's everyday
life experience.

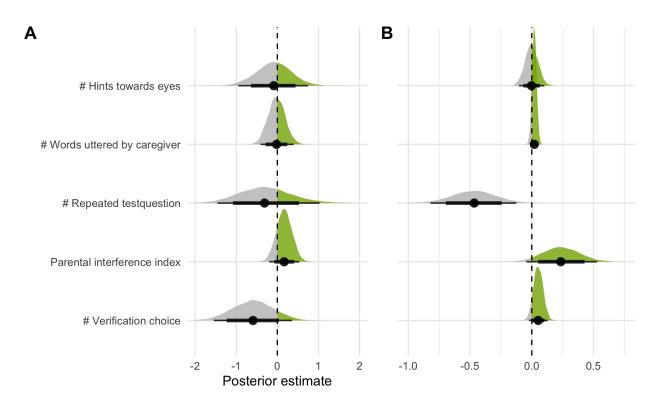

Figure 5. Model comparison for exploratory webcam coding of parental interference. Factors of parental interference and their influence on the probability of responding correctly. The graph shows the estimated density curves of a model's predictor coefficient. Models are ordered according to their WAIC scores in the trial-by-trial analysis, with the uppermost winning the model comparison. (A) Analysis on a trial-by-trial level. (B) Analysis on a subject level.

Webcam coding. Comparing the performances of children across our two data collection modes, we found that children participating remotely were slightly more precise. This difference was especially prominent in younger participants in the box version of the task. It is conceivable that caregivers were especially prone to influence the behavior of younger children. In the box version, caregivers might have had more opportunities to interfere since they carried out the clicking for their children. In an exploratory analysis, we coded parental behavior and environmental factors during remote unsupervised testing.

Due to the time consuming nature of hand coding videos frame by frame, we focused on

the subsample with the greatest performance difference between data collection modes: the 560 three-year-olds in the box version of the task (n = 16). We reasoned that if parental 561 interference cannot explain the greatest performance difference in our sample, the effects 562 would be negligible in the remaining sample. A trial was defined as the time between two 563 eye blinking sounds. We transcribed all utterances by parents and children and counted 564 the words uttered by each. We then classified the utterances into several categories: 565 question asked by child, repeated test questions by caregiver, hints towards agents (how 566 many times the caregivers guided the child's attention to the agent), hints towards eyes 567 (how many times the caregivers guided the child's attention to the agent's eyes), 568 verification of choice (how many times the caregiver questioned or double checked the 569 child's response), mentioning of screen (how many times the caregiver verbally guided the 570 child's attention to the screen), pointing to screen (how many times the caregiver pointed towards the screen), positive & negative feedback, motivational statements, and 572 incomprehensible utterances. In addition, we coded how many adults and children were present, whether a response click was obviously conducted by the caregiver themselves, and 574 whether children took a break during the trial. We conducted a model comparison to 575 estimate the effects of parental interference. Our null model explained the response 576 behavior by age, while including random effects for subject and target position (model 577 notation in R: correct ~ age + (1 | subjID) + (1 | targetPosition). 578

We compared this null model to models including the number of words uttered by the caregiver, number of repeated testquestions, verification of choice, or hints towards eyes as fixed effects. Furthermore, we calculated an parental interference index by summing up number of repeated testquestions, verification of choice, and hints towards eyes, with the sign matching the variable's direction of effect. Remaining variables that we coded for were

³ Attentive readers might notice that we simplified the structure of random effects. Compared to our models in the *Individual differences* and *External Validity* sections, this model does not include the random slope for symmetric target position within participants. We decided to do so since we had limited amount of data from few participants.

not included since there was not enough variation and/or occurrences in our sample. We 584 compared models using WAIC (widely applicable information criterion) scores and weights. 585 As an indicator of out-of-sample predictive accuracy, lower WAIC scores stand for a better 586 model fit. WAIC weights represent the probability that the model in question provides the 587 best out-of-sample prediction compared to the other models. On the trial level, the model 588 including the verification of choice as a main effect performed best: here, the less the 580 caregivers asked for children's responses again, the more likely children clicked on the 590 correct box. Interestingly, the effect reversed on a subject level - possibly due to greater 591 learning effects for the children that were most likely to click incorrectly in the beginning 592 and then receiving most parental comments. On the subject level, the model including 593 number of repeated test questions performed best: the more caregivers asked again where 594 the target landed, the more likely children were to respond to the incorrect box. In all cases, however, ELPD difference scores were smaller than their standard errors. Similarly, 95% CI of the model estimates included zero and were rather wide (Table ??). Therefore, we conclude that the effect of parental interference was negligable and could, most likely, 598 be explained as described above. 590

Appendix to external validity section.

Scoring of sibling variety scores. For assessing the external validity of our balloon finding task, we calculated two sibling variety scores based on the existing Theory of Mind literature. First, we followed the approach by Peterson (2000). Here, only-children as well as firstborns with siblings under one year scored 0 points; lastborns with siblings above 12 years scored 0.5 points; children with twins, firstborns with siblings over one year, and lastborns with at least one sibling under 13 years scored 1 point, middleborns with at least one older and younger sibling aged one to 12 years scored 2 points.

Second, we implemented the sibling variety score by Cassidy et al. (2005). The
authors adjusted the original score of Peterson (2000) in the following way: only-children
scored 0 points; children with a sibling under one year or above 12 years, and twins with no

Table 1
Model comparison for influences of children's social surrounding

Predictor	WAIC	SE_WAIC	Weight	ELPD_DIFF	SE_ELPD
Average hours spent in childcare per day	2,540.39	52.23	0.54	0.00	0.00
Peer exposure index	2,541.00	52.22	0.28	-0.30	0.92
# Children in household aged 0-18	$2,\!541.65$	52.30	0.02	-0.63	1.09
Sibling variety score (Cassidy et al., 2005)	$2,\!541.76$	52.33	0.01	-0.68	1.05
Sibling variety score (Peterson, 2000)	2,541.80	52.38	0.02	-0.71	1.10
Age of childcare entry	2,542.19	52.38	0.12	-0.90	1.32
# Children in household aged 1-12	2,542.26	52.34	0.00	-0.94	0.92
Null model	2,542.58	52.26	0.00	-1.09	0.79
# Household members	$2,\!543.46$	52.36	0.00	-1.54	0.97

Note. All models included random intercepts for each participant and each target position, and a random for symmetric target position within participants

other sibling scored 0.5 points; children with a sibling above one year or under 13 years scored 1 point; middleborns with at least one older and younger sibling aged one to 12 years scored 2 points. Twins with additional siblings scored depending on the age and number of their siblings.

The reasoning was that children between one and 13 years of age would engage in sibling play, while the youngest and most mature siblings would be less likely to participate in such. However, teenage siblings might provide opportunities for interesting discussions (Peterson, 2000).

WAIC scores and weights of the model comparison. As can be seen, ELPD difference scores are smaller than their respective standard errors. WAIC scores between models don't differ substantially (Table 1). All effects except when a child entered childcare positively influence performance.

Adult sample

640

647

Recruitment. We recruited participants using the online participant recruitment 624 service Prolific from the University of Oxford. Prolific's subject pool consists of a mostly 625 European and US-american sample although subjects from all over the world are included. 626 The recruitment platform realises ethical payment of participants, which requires 627 researchers to pay participants a fixed minimum wage of £5.00 (around US\$6.50 or €6.00) 628 per hour. We decided to pay all participants the same fixed fee which was in relation to the 629 estimated average time taken to complete the task. Prolific distributed our study link to 630 potential participants, while the hosting of the online study was done by local servers in 631 the Max Planck Institute for Evolutionary Anthropology, Leipzig. Therefore, study data 632 was saved only on our internal servers, while *Prolific* provided demographic information of 633 the participants. Participants' Prolific ID was forwarded to our study website using URL 634 parameters. This way, we could match participant demographic data to our study data. 635 The same technique was used to confirm study completion: we redirected participants from 636 our study website back to the *Prolific* website using URL parameters. We used *Prolific*'s 637 inbuilt prescreening filter to include only participants who were fluent in English and could 638 therefore properly understand our written and oral study instructions. 639

hedge version of our balloon finding task. The pre-registration can be found here:
https://osf.io/r3bhn. We recruited participants online by advertising the study on *Prolific*.

50 adults participated in the study. One additional subject returned their submission,
i.e., decided to leave the study early or withdrew their submission after study completion.

Data collection took place in May 2021. Participants were compensated with £1.25 for
completing the study. We estimated an average completion time of 6 minutes, resulting in

an estimated hourly rate of £10.00. In average, participants took 05:56min to complete the

study. Participants were required to complete the study on a tablet or desktop.

Study 1 - Validation hedge version. The aim of Study 1 was to validate the

Participation on mobile devices was disabled since the display would be too small and would harm click precision. It was indicated that the study required audio sound.

We stored *Prolific*'s internal demographic information, while not asking for additional personal information.

Study 2 - Validation box version. As in study 1, we recruited participants on

Prolific, and employed the same methodology. However, this time we focussed on

validating the box version of the task in an adult sample. Participants were presented with

eight boxes in which the target could land. 50 adults participated in the study. One

additional subject returned their submission, i.e., decided to leave the study early or

withdrew their submission after study completion. Data collection took place in June 2021.

Participants were compensated with £1.00 for completing the study. We estimated an

average completion time of 6 minutes, resulting in an estimated hourly rate of £10.00. In

average, participants took 04:43min to complete the study.

Study 3 - Reliability hedge version. In study 3 and 4, we assessed the 662 test-retest reliability of our balloon-finding task in an adult sample. The pre-registration 663 can be found here: https://osf.io/nu62m. We tested the same participants twice with a 664 delay of two weeks. The testing conditions were as specified in Study 1 and 2. However, 665 the target locations as well as the succession of animals and target colors was randomized 666 once. Each participant then received the same fixed randomized order of target location, 667 animal, and target color. Participants received 30 test trials without voice-over description. 668 so that each of the ten bins occurred exactly three times. 660

In addition to the beforementioned prescreening settings, we used a whitelist. *Prolific*has a so-called *custom allowlist prescreening filter* where one can enter the *Prolific* IDs of
participants who completed a previous study. Only these subjects are then invited to
participate in a study. This way, repeated measurements can be implemented, collecting
data from the same subjects at different points in time.

In a first round, 60 participants took part on the first testday. Additional two 675 subjects returned their submission, i.e., decided to leave the study early or withdrew their 676 submission after study completion. One additional participant timed out, i.e., did not 677 finish the survey within the allowed maximum time. The maximum time is calculated by 678 *Prolific*, based on the estimated average completion time. For this study, the maximum 679 time amounted to 41 minutes. For the first testday, participants were compensated with 680 £1.25. We estimated an average completion time of 9 minutes, resulting in an estimated 681 hourly rate of £8.33. In average, participants took 07:11min to complete the first part. 682

Of the 60 participants that completed testday 1, 41 subjects finished testday 2. One
additional participant timed out, i.e., did not finish the survey within the allowed
maximum time. Participants were compensated with £1.50 for completing the second part
of the study. We estimated an average completion time of 9 minutes, resulting in an
estimated hourly rate of £10. In average, participants took 06:36min to complete the
second part of the study.

Since we aimed for a minimum sample size of 60 subjects participating on both testdays, we reran the first testday with additional 50 participants. Additional seven subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. Two additional participants timed out, i.e., did not finish the survey within the allowed maximum time. Again, participants were compensated with £1.25 for completing the first part of the study (estimated average completion time 9 minutes, estimated hourly rate of £8.33). In average, participants took 06:51min to complete the first part.

Of the additional 50 participants that completed testday 1, 29 subjects finished testday 2. Again, participants were compensated with £1.50 for completing the second part of the study (estimated average completion time 9 minutes, estimated hourly rate of £10). In average, participants took 06:26min to complete the second part of the study.

Study 4 - Reliability box version. As in study 3, we recruited participants on Prolific, and employed the same methodology. However, this time participants were presented with the box version of the task. Participants received 32 test trials without voice-over description, so that each of the eight boxes occurred exactly four times. As in study 2, we employed eight boxes in which the target could land.

In a first round, 60 participants took part on the first testday. Additional five subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. For the first testday, participants were compensated with £1.25. We estimated an average completion time of 9 minutes, resulting in an estimated hourly rate of £8.33. In average, participants took 07:33min to complete the first part.

Of the 60 participants that completed testday 1, 41 subjects finished testday 2.

Participants were compensated with £1.50 for completing the second part of the study. We estimated an average completion time of 9 minutes, resulting in an estimated hourly rate of £10. In average, participants took 07:50min to complete the second part of the study.

Since we aimed for a minimum sample size of 60 subjects participating on both 716 testdays, we reran the first testday with additional 50 participants. Additional eight 717 subjects returned their submission, i.e., decided to leave the study early or withdrew their 718 submission after study completion. One additional participant timed out, i.e., did not 719 finish the survey within the allowed maximum time. Again, participants were compensated 720 with £1.25 for completing the first part of the study (estimated average completion time 9) 721 minutes, estimated hourly rate of £8.33). In average, participants took 07:37min to 722 complete the first part. 723

Of the additional 50 participants that completed testday 1, 28 subjects finished testday 2. Additional three subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. One additional

participant timed out, i.e., did not finish the survey within the allowed maximum time.

Again, participants were compensated with £1.50 for completing the second part of the

study (estimated average completion time 9 minutes, estimated hourly rate of £10). In

average, participants took 06:30min to complete the second part of the study.
