Abstract

In order to explain and predict the behavior of agents, we use social cognition: we represent and reason about other's perspectives, knowledge, intentions, beliefs and 11 preferences. Traditional measures of social cognition (e.g., false belief change-of-location 12 tasks), however, often lack satisfactory psychometric properties: they are not designed to capture variation between children and rely on low trial numbers, dichotomous measures, and group averages. This has profound implications on what these studies can show. Poor 15 measurement of social cognition on an individual level may conceal relations between 16 different aspects of cognition and may obscure developmental change. To fully understand 17 how social-cognitive abilities emerge and relate to each other, we need new tools that can 18 reliably measure individual differences. To approach this issue, we designed a balloon 19 finding task to study social cognition in young children and adults. We concentrate on an essential ability that is involved in many social-cognitive reasoning processes: gaze cue 21 understanding – the ability to locate and use the attentional focus of an agent. Our 22 interactive web interface works across devices and enables supervised and unsupervised, as well as in-person and remote testing. The implemented spatial layout allows for discrete as well as continuous measures of participants' click imprecision and is easily adoptable to 25 different study needs. Here we show that our task induces inter-individual differences in a child (N = XXX) and adult (N = XXX) sample. Our two study versions and data 27 collection modes yield comparable results that show substantial developmental gains: the older children are, the more accurately they locate the target. High internal consistency and test-test reliability estimates underline that the capured variation is systematic. Furthermore, we find first evidence for the external validity of our task: the measured performance in gaze cue understanding relates to children's real life social surrounding. Taken together, this work shows a promising way forward in the study of individual differences in social cognition and will help us explore the in(ter)dependence of our core social-cognitive processes in greater detail.

Measuring individual differences in the understanding of gaze cues across the lifespan

39 Introduction

- Idea for an opener :)
- Developmental psychology is facing a dilemma: many research questions are
- 42 questions about individual differences, yet, there is a lack of tasks to reliably measure these
- individual differences. For example ...
- why is social cognition important
- what methods are currently been used?: wellman
- what are common issues?
- what to aim at. individual differences in developmental psychology
- what characteristics should a new task fulfill? reliable tasks, variation needed, more
- 49 trials

50

- goal of the current project: standardized, easy to use continuous methods
- "Recently, it was suggested that a range of cognitive tasks may reliably measure
- ₅₂ group differences but not individual differences (Hedge et al., 2018). As cognitive tests are
- 53 commonly used to make inferences about individuals, it seems a worthwhile pursuit to
- 54 improve the reliability with which individual differences are assessed using these tests. To
- ⁵⁵ judge the success of such pursuits, accurate estimates of reliability are required." (Pronk,
- Molenaar, Wiers and Murre, 2021, p. 1) "Firstly, reliability is not only a function of task
- 57 and population sample but also of scoring algorithms." (Pronk, Molenaar, Wiers and
- Murre, 2021, p. 9) "Hence, we conclude that for the datasets included in our reanalysis,
- 59 cognitive tasks may well have been able to measure individual differences, but that these
- 60 differences may be relatively unstable over time (Kopp et al., 2021). In practice, this may
- 61 make cognitive tasks suitable for cross-sectional research of individual differences, but not
- for longitudinal research." (Pronk, Molenaar, Wiers and Murre, 2021, p. 10)

Rakoczy, H. (2022). Foundations of theory of mind and its development in early 63 childhood. Nature Reviews Psychology, 1–13. https://doi.org/10.1038/s44159-022-00037-z: 64 "The way humans view agents, be it others or themselves, differs radically from the way 65 humans view the rest of the world. This difference is because agents feel, perceive and 66 think. Agents see the world from their own subjective perspective and they rationally plan, 67 form intentions and act accordingly. This way of seeing others as rational subjects with 68 individual perspectives on the world is termed theory of mind (ToM)." (p. 1) "ToM also has specific real-life consequences. First, the development of ToM competence goes along with general measures of children's peer social skills in early and middle childhood. (...) 71 Second, ToM specifically predicts communicative competence. (...) Third, ToM 72 competence is related to the quality of peer relationships: children with more advanced 73 ToM are rated as more likeable and popular among their peers. Fourth, children who are more proficient at ToM tasks tend to act more prosocially, including comforting, sharing or helping other individuals. Finally, preschool ToM competence predicts achievement in primary school, a relationship that is possibly mediated by social competence, in that preschool ToM abilities enable subsequent social competence development, which in turn 78 contributes to school achievement." (p. 2) "Evidence for an emerging understanding of perception at 9 months of age comes from various sources. For example, children begin to 80 follow the gaze of other agents in systematic and differential ways: they follow an agent's 81 head turn only when the agent can actually see (has their eyes open rather than closed, or 82 wears a transparent rather than an opaque blindfold)." (p. 2) Developmental determinants: 83 executive function, language ("that" complementations), social (SES, siblings, 84 mind-minded parents) Implicit tasks: "A third class of implicit ToM tasks is interaction 85 tasks, in which participants are involved in a communicative or cooperative interaction with another agent. This agent forms a mental state (such as a true or false belief 87 regarding the contents of a box) and experimenters measure whether participants spontaneously take the agent's belief into account in their interaction with the agent (for

Task design

• face value of task (or maybe in intro already?)

94 Implementation

92

93

Our balloon finding task is presented as an interactive web app. The task is portable across devices and web browsers and does not require any installation. An advantage of online testing is that our testing procedure is standardized across participants. By using pre-recorded study instructions, no interaction with the experimenter is necessary during the study. The code is open-source (https://github.com/ccp-eva/gafo-demo) and a live demo version can be found under: https://ccp-odc.eva.mpg.de/gafo-demo/.

The web app was programmed in JavaScript, HTML5, CSS and PHP. For stimulus 101 presentation, a scalable vector graphic (SVG) composition was parsed. This way, the 102 composition scales according to the user's view port without loss of quality, while keeping 103 the aspect ratio and relative object positions constant. Furthermore, SVGs allow us to 104 define all composite parts of the scene (e.g., pupil of the agent) individually. This is needed 105 for precisely calculating exact pupil and target locations and sizes. Additionally, it makes it 106 easy to adjust the stimuli and, for example, add another agent to the scene. The web app 107 generates two file types: (1) a text file (.json) containing meta-data, trial specifications and 108 participants' click responses, and (2) a video file (.webm) of the participant's webcam 109 recording. These files can either be sent to a server or downloaded to the local device.

11 Stimuli

Our newly implemented task features an online game where children or adults are asked to search for a balloon. The events proceed as follows (see Figure 1B and C). An

animated agent (a sheep, monkey, or pig) looks out of a window of a house. A balloon (i.e., 114 target; blue, green, yellow, or red) is located in front of them. The target then falls to the 115 ground. At all times, the agent's gaze tracks the movement of the target. That is, the 116 pupils and iris of the agent move in a way that their center aligns with the center of the 117 target. While the distance of the target's flight depends on the final location, the target 118 moves at a constant speed. Participants are then asked to locate the target: they respond 119 by touching or clicking on the screen. Visual access to the target's true location is 120 manipulated by a hedge. Participants either have full, partial, or no visual access to the 121 true target location. When partial or no information about the target location is accessible, 122 participants are expected to use the agent's gaze as a cue. 123

To keep participants engaged and interested, the presentation of events is 124 accompanied by cartoon-like effects. Each trial starts with an attention-getter: an 125 eye-blinking sound plays while the pupils and iris of the agent enlarge (increase to 130%) 126 and change in opacity (decrease to 75%) for 0.3 sec. The landing of the target is 127 accompanied by a tapping sound. Once the target landed, the instructor's voice asks 128 "Where is the balloon?". For confirming the participant's click, a short plop sound plays 120 and a small orange circle appears at the location of choice. If no response is registered 130 within 5 secs after the target landed, an audio prompt reminds the participant to respond. 131

132 Trials

Trials differ in the amount of visual access that participants have to the final target position. Before the test trials start, participants complete four training trials during which they familiarize themselves with clicking the screen. In the first training trial, participants have full visual access to the target flight and the target's end location and are simply asked to click on the visible balloon. In the second and third training trials, participants have partial access: they witness the target flight but cannot see the target's end location. They are then asked to click on the hidden balloon, i.e., the location where they saw the

target land. In test trials, participants have no visual access to the target flight or the end location. Participants are expected to use the agent's gaze as a cue to locate the target.

The first trial of each type comprises a voice-over description of the presented events. The audio descriptions explicitly state that the agent is always looking at the target (see Appendix for audio script). After the four training trials, participants receive 15 test trials. The complete sequence of four training trials and 15 test trials can be easily completed within 5-10 minutes.

147 Study versions

We designed two study versions which differ in the final hiding place of the target 148 and, consequently, on the outcome measure: a hedge version (continuous) and a box version 149 (discrete). Both versions use the same first training trial and then differ in the consecutive 150 training and test trials. In the hedge version, participants have to indicate their estimated 151 target location directly on a hedge. Here, the dependent variable is imprecision, which is 152 defined as the absolute difference between the target center and the x coordinate of the 153 participant's click. In the box version, the target lands in a box and participants are asked 154 to click on the box that hides the target. Researchers have the choice how many boxes are shown: one up to eight boxes can be displayed as potential hiding locations. Here, we use a categorical outcome (i.e., which box was clicked) to calculate the proportion of correct 157 responses. Note that in the test trials of both versions, the target flight is covered by a 158 hedge. In the hedge version, the hedge then shrinks to a minimum height required to cover 159 the target's end location. In the box version, the hedge shrinks completely. The boxes then 160 hide the target's final destination (see Figure 1B and C). 161

62 Randomization

All agents and target colors appear equally often and are not repeated in more than two consecutive trials. The randomization of the target end location depends on the study

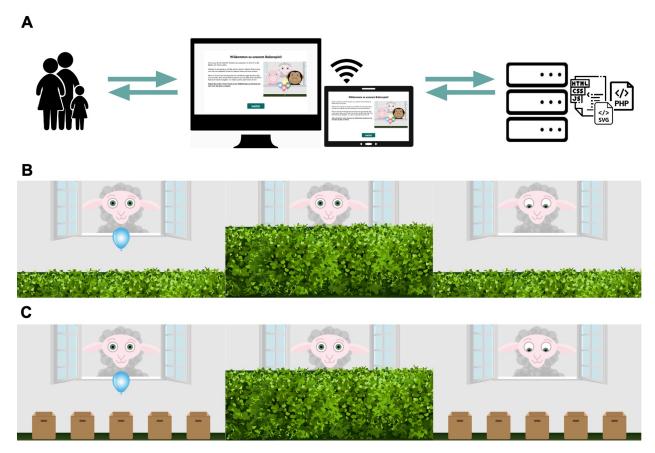

Figure 1. Study setup. (A) Infrastructure for online testing. (i) Subjects aged 3 – 99+ can participate. Data collection can take place anywhere: online, in kindergartens or research labs. (ii) The task is presented as a website that works across devices. (iii) The scripts for the website and the recorded data are stored on secure local servers. (B) Hedge version (continuous) of the balloon finding task. (i) The agent stands in a window with the target in front of them. (ii) A hedge grows and covers the target. (iii) The target falls to a random location on the ground. The agent's eyes track the movement of the target. (C) Box version (discrete) of the balloon finding task. Number of boxes (min. 1; max. 8) as potential hiding locations can be set according to the researcher's need.

version. In the hedge version, the full width of the screen is divided into ten bins. Exact coordinates within each bin are then randomly generated. In the box version, the target randomly lands in one of the boxes. As with agent and color choice, each bin/box occurs equally often and can only occur twice in a row.

Individual differences

Our first aim was to assess whether our balloon finding task induces inter-individual variation in a child and adult sample. Furthermore, we were interested in how the data collection mode influences responses.

Methods, sample size and analysis were pre-registered: https://osf.io/snju6 (child sample) and https://osf.io/r3bhn (adult sample). Participants were equally distributed across the two study versions. The study was approved by an internal ethics committee at the Max Planck Institute for Evolutionary Anthropology. Data was collected between May and October 2021.

178 Participants

169

We collected data from an in-person child sample, a remote child sample, and a remote adult sample. In-person testing with children took place in kindergartens in Leipzig, Germany. The in-person child sample consisted of 120 children, including 40 3-year-olds (mean = 41.45 months, SD = 3.85, range = 36 - 47, 22 girls), 40 4-year-olds (mean = 54.60 months, SD = 3.10, range = 48 - 59, 19 girls), and 40 5-year-olds (mean = 66.95 months, SD = 3.39, range = 60 - 71, 22 girls).

For our remote child sample, we recruited families via an internal database. The remote child sample included 147 children, including 45 3-year-olds (mean = 42.62 months, SD = 3.35, range = 36 - 47, 14 girls), 47 4-year-olds (mean = 52.64 months, SD = 3.40, range = 48 - 59, 25 girls), and 55 5-year-olds (mean = 65.11 months, SD = 3.77, range =

60 - 71, 27 girls). Children in our sample grow up in an industrialized, urban
Central-European context. Information on socioeconomic status was not formally recorded,
although the majority of families come from mixed, mainly mid to high socioeconomic
backgrounds with high levels of parental education.

Adults were recruited via *Prolific*. *Prolific* is an online participant recruitment service from the University of Oxford with a predominantly European and US-american subject pool. Participants consisted of 50 and 50 English-speakers with an average age of 31.92 and 30.76 years (SD = 12.15 and 9.12, range = 18 and 19 - 63 and 59, 36 and 28 females). For completing the study, subjects were payed above the fixed minimum wage (in average £10.00 per hour).

199 Procedure

Children in our in-person sample were tested on a tablet in a quiet room in their 200 kindergarten. An experimenter guided the child through the study. Children in the remote 201 sample received a personalized link to the study website and families could participate at 202 any time or location they wanted. In the beginning of the online study, families were 203 invited to enter our "virtual institute" and were welcomed by an introductory video of the 204 study leader, shortly describing the research background and further procedure. Then, 205 caregivers were informed about data security and were asked for their informed consent. 206 They were asked to enable the sound and seat their child centrally in front of their device. 207 Before the study started, families were instructed how to setup their webcam and enable 208 the recording permissions. We stressed that caregivers should not help their children. Study participation was video recorded whenever possible in order to ensure that the 210 answers were generated by the children themselves. Depending on the participant's device, the website automatically presented the hedge or box version of the study. For families that 212 used a tablet with touchscreen, the hedge version was shown. Here, children could directly 213 click on the touchscreen themselves to indicate where the target is. For families that used a 214

computer without touchscreen, the website presented the box version of the task. We
assumed that younger children in our sample would not be acquainted with the usage of a
computer mouse. Therefore, we asked children to point to the screen, while caregivers were
asked to act as the "digital finger" of their children and click on the indicated box.

All participants received 15 test trials. In the box version, we decided to adjust the task difficulty according to the sample: children were presented with five boxes while adults were presented with eight boxes as possible target locations.

Analysis

All test trials without voice over description were included in our analyses. We ran all analyses in R version 4.1.3 (2022-03-10) (R Core Team, 2022). Regression models were fit as Bayesian generalized linear mixed models (GLMMs) with default priors for all analyses, using the function brm from the package brms (Bürkner, 2017, 2018).

To estimate the developmental trajectory of gaze cue understanding and the effect of 227 data collection mode, we fit a GLMM predicting the task performance by age (in months, 228 z-transformed) and data collection mode (reference category: in-person supervised). The model included random intercepts for each participant and each target position, and a 230 random slope for symmetric target position within participants (model notation in R: performance ~ age + datacollection + (symmetricPosition | subjID) + (1 | 232 targetPosition)). Here, targetPosition refers to the exact bin/box of the target, while 233 symmetricPosition refers to the absolute distance from the stimulus center (i.e., smaller 234 value meaning more central target position). We expected that trials could differ in their 235 difficulty depending on the target centrality and that these these item effects could vary 236 between participants. 237

For the hedge version, performance was defined as the absolute click distance between the target center and the click X coordinate, scaled according to target widths, and modeled by a lognormal distribution. For the box version, the model predicted correct responses (0/1) using a Bernoulli distribution with a logit link function. We inspected the posterior distribution (mean and 95% Confidence Interval (CI)) for the age and data collection estimates.

244 Results

261

We found a strong developmental effect: with increasing age, participants got more 245 and more accurate in locating the target. In the hedge version, children's click imprecision 246 decreased with age, while, in the box version the proportion of correct responses increased 247 (see Figure 2A and F). Most participants in the box version performed above chance level. 248 By the end of their sixth year of life, children came close to the adult's proficiency level. 249 Most importantly, however, we found substantial inter-individual variation across study 250 versions and age groups. For example, some three-year-olds were more precise in their 251 responses than some five-year-olds. Even though variation is smaller, we even find 252 inter-individual differences in the adult sample. 253

As Figure 2A and F show, our remotely collected child data resembled the data from
the kindergarten sample. We found evidence that responses of children participating
remotely were slightly more precise. This difference was mainly driven by the younger
participants and especially prominent in the box version of the task. It is conceivable that
caregivers were especially prone to influence the behavior of younger children. In the box
version, caregivers might have had more opportunities to interfere since they carried out
the clicking for their children.¹

Our GLMM analysis corroborated the visual inspection of the data: in the hedge

 $^{^1}$ In an exploratory analysis, we coded parental behavior and environmental factors during remote unsupervised testing. We focused on the subsample with the greatest performance difference between data collection modes: the three-year-olds in the box version of the task (n = 16). We reasoned that if parental interference cannot explain the greatest performance difference in our sample, the effects would be negligible in the remaining sample. Based on our model comparison, we conclude that there is no clear evidence of a stable effect of parental interference. See Supplements for further detail.

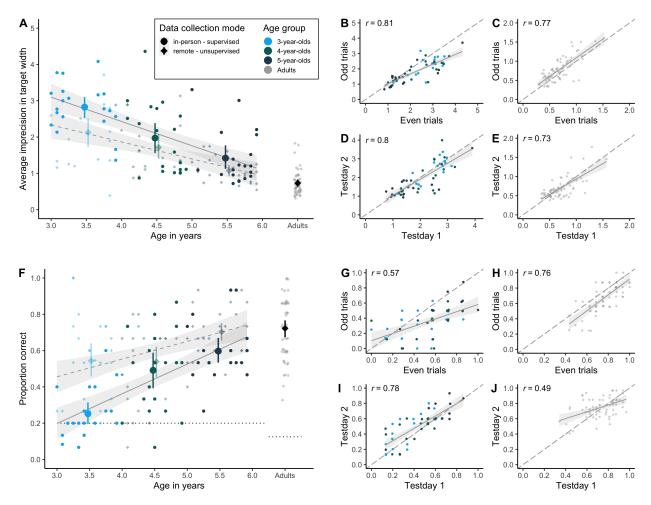

Figure 2. Measuring inter-individual variation. (A) Developmental trajectory in continuous hedge version. Performance is measured as average imprecision, i.e., the absolute distance between the target's center and the participant's click. The unit of imprecision is counted in the width of the target, i.e., a participant with an imprecision of 1 clicked in average one target width to the left or right of the true target center. (B) Internal consistency (odd-even split) in hedge child sample. (C) Internal consistency in hedge adult sample. (D) Test-retest reliability in hedge child sample. (E) Test-retest reliability in hedge adult sample. (F) Developmental trajectory in discrete box version. Performance is measured as the proportion of correct responses, i.e., how many times the participant clicked on the box that actually contained the target. Dotted black line shows level of performance expected by chance (for child sample 20%, i.e., 1 out of 5 boxes; for adult sample 12.5%, i.e., 1 out of 8 boxes). (G) Internal consistency (odd-even split) in box child sample. (H) Internal consistency in box adult sample. (I) Test-retest reliability in box child sample. (J) Test-retest reliability in box adult sample. Regression lines with 95% CI as smoothed mean based on a linear model, with Pearson's correlation coefficient r. Large points with 95% CI (based on non-parametric bootstrap) represent performance means by age group (binned by year). Small points show the mean performance for each subject. Shape of data points represents data collection mode: opaque circles for in-person supervised data collection, translucent diamonds for remote unsupervised data collection. Color of data points denotes age group.

version, the estimates for age ($\beta = -0.32$; 95% CI [-0.41; -0.24]) and data collection mode -0.32 (95% CI [-0.49; -0.14]) were negative and reliably different from zero. In the box version, the estimate of age ($\beta = 0.63$ (95% CI [0.40; 0.88]) and the estimate of data collection mode ($\beta = 1.12$ (95% CI [0.69; 1.57]) were positive and reliably different from zero. Note that even though confidence intervals from the data collection estimates were wide, the effect was positive and reliably different from zero in a way that our remote sample performed more accurately than our in-person sample.

269 Discussion

274

Our task induced inter-individual variation in both adults and children. With increasing age, participants got more and more precise in locating the target. Furthermore, we found a comparable developmental trajectory for an unsupervised remote child sample.

This illustrates the flexibility of the task.

Internal consistency and retest reliability

As a next step, we aimed at investigating whether the variation that we captured with our balloon finding task is reliable. We assessed internal consistency (split-half reliability) and test-retest reliability. Data collection and analysis were pre-registered (can be found here: https://osf.io/xqm73 for child sample, and https://osf.io/nu62m adult sample). Participants were equally distributed across the two study versions. The study was approved by an internal ethics committee at the Max Planck Institute for Evolutionary Anthropology. Data was collected between July 2021 and April 2022.

282 Participants

Participants were recruited in the same way as in the previous study. The child sample consisted of 106 children, including 35 3-year-olds (mean = 42.57 months, SD =

285 2.98, range = 38 - 47, 17 girls), 38 4-year-olds (mean = 53.77 months, SD = 3.16, range = 48 - 59, 20 girls), and 33 5-year-olds (mean = 66.12 months, SD = 3.36, range = 61 - 71, 17 girls).

The adult sample consisted of 70 and 66 English-speakers with an average age of 25.43 and 26.05 years (SD = 6.43 and 9.44, range = 18 and 18 - 51 and 71, 45 and 42 females).

290 Procedure

We applied the same procedure as in the first study, with the following differences. 291 Participants completed the study twice, with a delay of 14 ± 3 days. The target locations 292 as well as the succession of agents and target colors was randomized once and then held 293 constant across participants. The child sample received 15 test trials. In the hedge version, 294 each bin occurred once, making up ten of the test trials. For the remaining five test trials, 295 we repeated one out of two adjacent bins (i.e., randomly chose between bin 1 & 2, bin 3 & 296 4, etc). In the box version, we ensured that each of the five boxes occurred exactly three 297 times. For the remaining training trials, we repeated a fixed order of four random 298 bins/boxes. Adults in the hedge version received 30 test trials, each of the ten bin 290 occurring exactly three times. Adults in the box version received 32 test trials with each of 300 the eight boxes occurring exactly four times.

$\mathbf{Analysis}$

We assessed reliability in two ways. First, we focused on the internal consistency by
calculating splithalf reliability coefficients. For each subject, trials were split into odd and
even trials, performance was aggregated and then correlated using *Pearson* coefficients. For
this, we used the data of the first test day. Performance was defined according to study
version: in the hedge version, performance referred to the mean absolute difference between
the target center and the click coordinate, scaled according to target widths; in the box

version, we computed the mean proportion of correct choices. Pronk, Molenaar, Wiers, and 309 Murre (2021) recently compared various methods for computing split-half reliability that 310 differ in how the trials are split into parts and whether they are combined with 311 stratification by task design. To compare our traditional approach of a simple odd-even 312 split, we additionally calculated reliability estimates using first-second, odd-even, 313 permutated, and Monte Carlo splits without and with stratification by target position. 314 First-second and odd-even splits belong to single sample methods, since each participant 315 has a single pair of performance scores, while permutated (without replacement) and 316 Monte Carlo (with replacement) splits make use of resampling. Analyses were run using 317 the function by split from the splithalfr package (Pronk et al., 2021). 318

Second, we assessed the test-retest reliability. We calculated performance scores 319 (depending on study version as described above) for each participant in each test session 320 and correlated them using *Pearson* correlation coefficients. Furthermore, for our child 321 sample we report an age-corrected correlation between the two test days using a GLMM 322 based approach (Rouder & Haaf, 2019). We fit trial by trial data with a fixed effect of age, 323 a random intercept for each subject and a random slope for test day (model notation in R: 324 performance ~ age (0 + reliday | subjID)). For the hedge version, performance was 325 modeled by a lognormal distribution, while the model for the box version used a Bernoulli 326 distribution with a logit link function. The model computes a correlation between the 327 participant specific estimates for each test day. This can be interpreted as the test-retest 328 reliability. By using this approach, we do not need to compromise on data aggregation and, therefore, loss of information. Most importantly, the model allows us to get an age-independent estimate for reliability. This rules out the possibility that a high 331 correlation between test days arises from domain general cognitive development instead of 332 study-specific inter-individual differences [m: das noch bisschen konkreter machen. also 333 wann würden wir eine hohe korrelation sehen und wie kümmert sich das model da drum]. 334

335 Results

We found that our balloon finding task induced systematic variation: splithalf and 336 test-retest reliability was high for most samples. For the internal consistency, we show 337 traditional odd-even splits on our data and the corresponding *Pearson* correlation 338 coefficients in Figure 2B, C, G and H. Figure 3 compares splithalf reliability coefficients by 339 splitting and stratification method (Pronk et al., 2021). In the hedge version, the splithalf 340 reliability coefficients ranged from 0.57 to 0.84. In the box version, splithalf reliability 341 coefficients ranged from 0.49 to 0.76. Similarly to the results of Pronk et al. (2021), we 342 found that more robust splitting methods that are less prone to task design or time 343 confounds yielded higher reliability coefficients. In the majority of cases, stratifying by 344 target position lead to similar or even higher estimates compared to no stratification. As 345 might be expected, we found higher coefficients for the samples with higher variation, i.e., 346 for our continuous hedge version of the task.

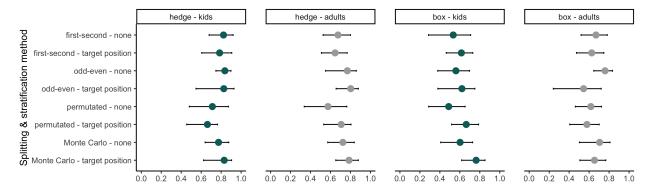

Figure 3. Internal Consistency. Reliability coefficients per splitting method, stratification level, study version and age group. Error bars show the 95% confidence intervals of the coefficient estimates, calculated with the function by_split from the splithalfr package (Pronk et al., 2021).

For the test-retest reliability, we show the association between raw performance scores of the two test days and corresponding Pearson correlation coefficients in Figure 2D, E, I and J.²

 $^{^2}$ In the hedge version, we excluded one 5-year-old child from the test-retest analysis. The performance of

The age-corrected, GLMM based retest reliabilities for children yielded similar results. In hedge version it was 0.90 (95% CI [0.68;1.00]). In the box version it was 0.92 (95% CI [0.70;1.00]).

Discussion

Our results indicated that the measured variation was systematic. As could be
expected, the continuous measure of the hedge version yielded higher reliability estimates
than the discrete box version. For children, the model based reliability estimates showed
that the task did capture individual differences even when correcting for age. This
corroborates what we already see in Figure 2: there was a clear overlap between age
groups, indicating that age is predictive of performance for the mean, but is not the main
source of individual differences.

362 Validity

Our third aim was to assess whether the captured individual variation in gaze cue understanding relates to factors in children's real live social environment [m: kurz sagen warum wir das erwarten - also dass frühere studien hier links sehen (zitieren) und die mit anderen measures of social cognition auch finden. Daher sehen wir das als indikator für validität, wenn wir das auch finden.]

366

For this exploratory analysis, we included all children of the aforementioned samples where families filled out a short demographic questionnaire. This subsample consisted of 137 children, including 42 3-year-olds (mean = 43.04 months, SD = 3.25, range = 36 - 47,

the mentioned child was 3 standard deviations above the mean on both test days. Including the child yielded a *Pearson* correlation coefficient of r = 0.87.

 $_{372}$ 23 girls), 46 4-year-olds (mean = 54.43 months, SD = 2.76, range = 48 - 59, 34 girls), and $_{373}$ 49 5-year-olds (mean = 66.25 months, SD = 3.47, range = 60 - 71, 27 girls).

Procedure Procedure

Families of our kindergarten and online child sample were asked to fill out a brief
demographic questionnaire. We asked for (1) the total number of household members, (2)
the number of children, (3) age of the other children, (4) whether the child was in day care,
and if yes, (5) since when and (6) for how long on an average day.

379 Analysis

To estimate the effects of social surrounding on gaze cue understanding, we fit 380 GLMMs predicting the task performance by each of our questionnaire variables, controlling 381 for age (in months, z-transformed), data collection mode (reference category: in-person 382 supervised) and study version (reference category: hedge version). The models included 383 random intercepts for each participant and each target position, and a random slope for 384 symmetric target position within participants. Therefore, our null model closely resembled 385 the structure from our first analysis (see Analysis section of Does the balloon finding task 386 induce variation?; here: performance ~ age + datacollection + studyversion + 387 (symmetricPosition | subjID) + (1 | targetPosition)). In order to combine data of 388 our two study versions, we transformed continuous click responses from the hedge version 389 into a discrete outcome. For the target position, we categorized two adjacent bins as one 390 imaginary box. To measure participants' performance, we created imaginary box boundaries around the target's landing position and examined whether the participant's click response fell into this imaginary box. Across the two study versions, we could 393 consequently model the participant's correct response (0/1) using a Bernoulli distribution 394 with a logit link function. For model comparisons, we ran separate models, each with one 395 of the following predictors as a fixed effects added to the null model: number of household 396

members, number of children aged 0-18 in household, number of children aged 1-12 in 397 household, hours spent in childcare each day, and age when subject entered childcare. In 398 addition, we calculated three index scores. First, we calculated a sibling variety score 399 according to Peterson (2000). Second, we implemented the modified version of Cassidy, 400 Fineberg, Brown, and Perkins (2005) (for more details, see Supplements). Third, based on 401 our own data exploration, we calculated the amount of peer exposure determined as the 402 number of siblings and the average hours spent in childcare (both z-transformed). We 403 compared the models using WAIC (widely applicable information criterion) scores and weights (McElreath, 2020). As an indicator of out-of-sample predictive accuracy, lower 405 WAIC scores stand for a better model fit. WAIC weights represent the probability that the 406 model in question provides the best out-of-sample prediction compared to the other models. 407

408 Results

The model including our peer exposure index, as defined as the number of other 409 children in the household and average hours spent in childcare, showed the best 410 out-of-sample predictive accuracy. Note that we did not find a great difference in WAIC 411 scores between the compared models (see Supplements for WAIC scores and weights). The 412 model estimates were all considerably smaller than estimates of age, study version and 413 data collection, and all 95% CIs included zero. For example, for our winning model, we 414 found a peer exposure estimate of $\beta = 0.16$ (95% CI [-0.03; 0.36]), with the estimates of 415 age being $\beta = 0.58$ (95% CI [0.39; 0.77]), data collection mode being $\beta = 0.96$ (95% CI [0.56; 416 1.37]), and study version $\beta = 1.84$ (95% CI [0.26; 3.56]). Nevertheless, a general pattern emerges: exposure to a more variable social environment positively influenced children's 418 gaze cue understanding. The number of people and, more specifically, children, as well as 419 the more diverse their age, the more likely children were to understand the agent's gaze 420 cue. The only predictor resulting in a negative estimate was the age at which a participant 421 entered childcare, i.e., the later a child entered, the better performance in the task. 422

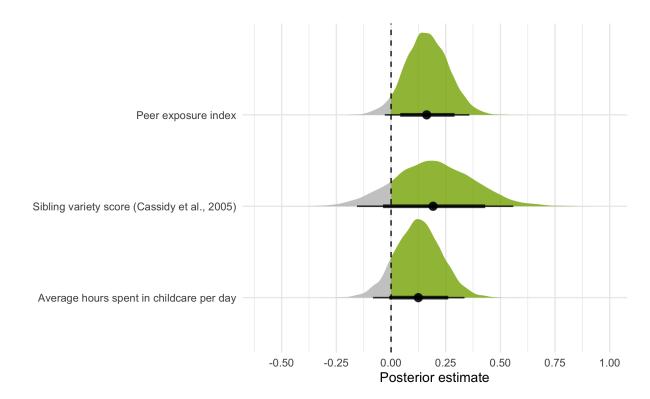

Figure 4. External validity of the balloon finding task. Factors of children's social surroundings and their influence on the probability of responding correctly. Models are ordered according to their WAIC scores, with the uppermost winning the model comparison. The graph shows the estimated density curves of a model's predictor coefficient. Only models performing better than our null model are included in the graph.

Discussion

In line with previous research, We found that factors of children's social surrounding influenced their gaze cue understanding. Even though the effects are small and confidence intervals wide, it is remarkable that we were able to detect relationships between this fundamental social-cognitive ability and very distant, real life variables [m: das ein bisschen aufdröseln - also sagen dass frühere tassk sich komplexere sahcen angeguckt haben und wir aber schon sehen, dass es schienbar systeamtische sachen gibt bei den einfachen dingen die wir hier messen].

431 Discussion

We were able to show that our balloon finding task measures inter-individual
variation between children and adults, alike. Our results suggest that the measured
variation is systematic during the course of the same and different test days. Impressively,
gaze cue understanding as measured by our task related to factors in children's everyday
life experience.

437 Limitations

Future development / extending the task

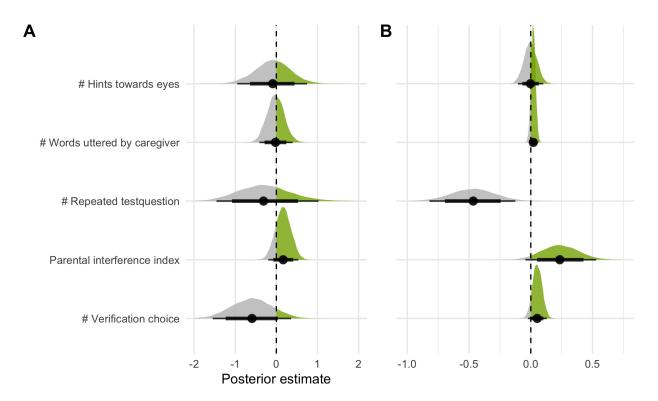

Figure 5. Model comparison for exploratory webcam coding of parental interference. Factors of parental interference and their influence on the probability of responding correctly. The graph shows the estimated density curves of a model's predictor coefficient. Models are ordered according to their WAIC scores in the trial-by-trial analysis, with the uppermost winning the model comparison. (A) Analysis on a trial-by-trial level. (B) Analysis on a subject level.

Webcam coding. Comparing the performances of children across our two data collection modes, we found that children participating remotely were slightly more precise. This difference was especially prominent in younger participants in the box version of the task. It is conceivable that caregivers were especially prone to influence the behavior of younger children. In the box version, caregivers might have had more opportunities to interfere since they carried out the clicking for their children. In an exploratory analysis, we coded parental behavior and environmental factors during remote unsupervised testing.

Due to the time consuming nature of hand coding videos frame by frame, we focused on

the subsample with the greatest performance difference between data collection modes: the three-year-olds in the box version of the task (n = 16). We reasoned that if parental 496 interference cannot explain the greatest performance difference in our sample, the effects 497 would be negligible in the remaining sample. A trial was defined as the time between two 498 eye blinking sounds. We transcribed all utterances by parents and children and counted 499 the words uttered by each. We then classified the utterances into several categories: 500 question asked by child, repeated test questions by caregiver, hints towards agents (how 501 many times the caregivers guided the child's attention to the agent), hints towards eyes 502 (how many times the caregivers guided the child's attention to the agent's eyes), 503 verification of choice (how many times the caregiver questioned or double checked the 504 child's response), mentioning of screen (how many times the caregiver verbally guided the 505 child's attention to the screen), pointing to screen (how many times the caregiver pointed towards the screen), positive & negative feedback, motivational statements, and incomprehensible utterances. In addition, we coded how many adults and children were present, whether a response click was obviously conducted by the caregiver themselves, and 509 whether children took a break during the trial. We conducted a model comparison to 510 estimate the effects of parental interference. Our null model explained the response 511 behavior by age, while including random effects for subject and target position (model 512 notation in R: correct ~ age + (1 | subjID) + (1 | targetPosition). 513

We compared this null model to models including the number of words uttered by the
caregiver, number of repeated testquestions, verification of choice, or hints towards eyes as
fixed effects. Furthermore, we calculated an parental interference index by summing up
number of repeated testquestions, verification of choice, and hints towards eyes, with the
sign matching the variable's direction of effect. Remaining variables that we coded for were

³ Attentive readers might notice that we simplified the structure of random effects. Compared to our models in the *Individual differences* and *External Validity* sections, this model does not include the random slope for symmetric target position within participants. We decided to do so since we had limited amount of data from few participants.

not included since there was not enough variation and/or occurrences in our sample. We 519 compared models using WAIC (widely applicable information criterion) scores and weights. 520 As an indicator of out-of-sample predictive accuracy, lower WAIC scores stand for a better 521 model fit. WAIC weights represent the probability that the model in question provides the 522 best out-of-sample prediction compared to the other models. On the trial level, the model 523 including the verification of choice as a main effect performed best: here, the less the 524 caregivers asked for children's responses again, the more likely children clicked on the 525 correct box. Interestingly, the effect reversed on a subject level - possibly due to greater 526 learning effects for the children that were most likely to click incorrectly in the beginning 527 and then receiving most parental comments. On the subject level, the model including 528 number of repeated test questions performed best: the more caregivers asked again where 529 the target landed, the more likely children were to respond to the incorrect box. In all cases, however, ELPD difference scores were smaller than their standard errors. Similarly, 95% CI of the model estimates included zero and were rather wide (Table 1). Therefore, we conclude that the effect of parental interference was negligable and could, most likely, be 533 explained as described above. 534

Appendix to external validity section.

535

Scoring of sibling variety scores. For assessing the external validity of our balloon finding task, we calculated two sibling variety scores based on the existing Theory of Mind literature. First, we followed the approach by Peterson (2000). Here, only-children as well as firstborns with siblings under one year scored 0 points; lastborns with siblings above 12 years scored 0.5 points; children with twins, firstborns with siblings over one year, and lastborns with at least one sibling under 13 years scored 1 point, middleborns with at least one older and younger sibling aged one to 12 years scored 2 points.

Second, we implemented the sibling variety score by Cassidy et al. (2005). The
authors adjusted the original score of Peterson (2000) in the following way: only-children
scored 0 points; children with a sibling under one year or above 12 years, and twins with no

other sibling scored 0.5 points; children with a sibling above one year or under 13 years scored 1 point; middleborns with at least one older and younger sibling aged one to 12 years scored 2 points. Twins with additional siblings scored depending on the age and number of their siblings.

The reasoning was that children between one and 13 years of age would engage in sibling play, while the youngest and most mature siblings would be less likely to participate in such. However, teenage siblings might provide opportunities for interesting discussions (Peterson, 2000).

WAIC scores and weights of the model comparison. As can be seen, ELPD
difference scores are smaller than their respective standard errors. WAIC scores between
models don't differ substantially (Table 2). All effects except when a child entered
childcare positively influence performance.

Note. All models included random intercepts for each participant and each target position, and a random slope for symmetric target position within participants

558 Adult sample

Recruitment. We recruited participants using the online participant recruitment 559 service Prolific from the University of Oxford. Prolific's subject pool consists of a mostly 560 European and US-american sample although subjects from all over the world are included. 561 The recruitment platform realises ethical payment of participants, which requires 562 researchers to pay participants a fixed minimum wage of £5.00 (around US\$6.50 or €6.00) per hour. We decided to pay all participants the same fixed fee which was in relation to the 564 estimated average time taken to complete the task. Prolific distributed our study link to 565 potential participants, while the hosting of the online study was done by local servers in the Max Planck Institute for Evolutionary Anthropology, Leipzig. Therefore, study data was saved only on our internal servers, while *Prolific* provided demographic information of the participants. Participants' Prolific ID was forwarded to our study website using URL 569 parameters. This way, we could match participant demographic data to our study data. 570 The same technique was used to confirm study completion: we redirected participants from 571 our study website back to the *Prolific* website using URL parameters. We used *Prolific*'s

575

inbuilt prescreening filter to include only participants who were fluent in English and could therefore properly understand our written and oral study instructions.

Study 1 - Validation hedge version. The aim of Study 1 was to validate the

hedge version of our balloon finding task. The pre-registration can be found here: 576 https://osf.io/r3bhn. We recruited participants online by advertising the study on *Prolific*. 577 50 adults participated in the study. One additional subject returned their submission. 578 i.e., decided to leave the study early or withdrew their submission after study completion. 579 Data collection took place in May 2021. Participants were compensated with £1.25 for 580 completing the study. We estimated an average completion time of 6 minutes, resulting in 581 an estimated hourly rate of £10.00. In average, participants took 05:56min to complete the 582 study. Participants were required to complete the study on a tablet or desktop. 583 Participation on mobile devices was disabled since the display would be too small and 584 would harm click precision. It was indicated that the study required audio sound. 585

We stored *Prolific*'s internal demographic information, while not asking for additional personal information.

Study 2 - Validation box version. As in study 1, we recruited participants on

Prolific, and employed the same methodology. However, this time we focussed on

validating the box version of the task in an adult sample. Participants were presented with

eight boxes in which the target could land. 50 adults participated in the study. One

additional subject returned their submission, i.e., decided to leave the study early or

withdrew their submission after study completion. Data collection took place in June 2021.

Participants were compensated with £1.00 for completing the study. We estimated an

average completion time of 6 minutes, resulting in an estimated hourly rate of £10.00. In

average, participants took 04:43min to complete the study.

Study 3 - Reliability hedge version. In study 3 and 4, we assessed the
test-retest reliability of our balloon-finding task in an adult sample. The pre-registration

624

can be found here: https://osf.io/nu62m. We tested the same participants twice with a
delay of two weeks. The testing conditions were as specified in Study 1 and 2. However,
the target locations as well as the succession of animals and target colors was randomized
once. Each participant then received the same fixed randomized order of target location,
animal, and target color. Participants received 30 test trials without voice-over description,
so that each of the ten bins occurred exactly three times.

In addition to the beforementioned prescreening settings, we used a whitelist. *Prolific*has a so-called *custom allowlist prescreening filter* where one can enter the *Prolific* IDs of
participants who completed a previous study. Only these subjects are then invited to
participate in a study. This way, repeated measurements can be implemented, collecting
data from the same subjects at different points in time.

In a first round, 60 participants took part on the first testday. Additional two 610 subjects returned their submission, i.e., decided to leave the study early or withdrew their 611 submission after study completion. One additional participant timed out, i.e., did not 612 finish the survey within the allowed maximum time. The maximum time is calculated by 613 Prolific, based on the estimated average completion time. For this study, the maximum 614 time amounted to 41 minutes. For the first testday, participants were compensated with 615 £1.25. We estimated an average completion time of 9 minutes, resulting in an estimated 616 hourly rate of £8.33. In average, participants took 07:11min to complete the first part. 617

Of the 60 participants that completed testday 1, 41 subjects finished testday 2. One additional participant timed out, i.e., did not finish the survey within the allowed maximum time. Participants were compensated with £1.50 for completing the second part of the study. We estimated an average completion time of 9 minutes, resulting in an estimated hourly rate of £10. In average, participants took 06:36min to complete the second part of the study.

Since we aimed for a minimum sample size of 60 subjects participating on both

testdays, we reran the first testday with additional 50 participants. Additional seven subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. Two additional participants timed out, i.e., did not finish the survey within the allowed maximum time. Again, participants were compensated with £1.25 for completing the first part of the study (estimated average completion time 9 minutes, estimated hourly rate of £8.33). In average, participants took 06:51min to

Of the additional 50 participants that completed testday 1, 29 subjects finished testday 2. Again, participants were compensated with £1.50 for completing the second part of the study (estimated average completion time 9 minutes, estimated hourly rate of £10). In average, participants took 06:26min to complete the second part of the study.

Study 4 - Reliability box version. As in study 3, we recruited participants on

Prolific, and employed the same methodology. However, this time participants were

presented with the box version of the task. Participants received 32 test trials without

voice-over description, so that each of the eight boxes occurred exactly four times. As in

study 2, we employed eight boxes in which the target could land.

In a first round, 60 participants took part on the first testday. Additional five subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. For the first testday, participants were compensated with £1.25. We estimated an average completion time of 9 minutes, resulting in an estimated hourly rate of £8.33. In average, participants took 07:33min to complete the first part.

Of the 60 participants that completed testday 1, 41 subjects finished testday 2.

Participants were compensated with £1.50 for completing the second part of the study. We
estimated an average completion time of 9 minutes, resulting in an estimated hourly rate of
£10. In average, participants took 07:50min to complete the second part of the study.

666

Since we aimed for a minimum sample size of 60 subjects participating on both 651 testdays, we reran the first testday with additional 50 participants. Additional eight 652 subjects returned their submission, i.e., decided to leave the study early or withdrew their 653 submission after study completion. One additional participant timed out, i.e., did not 654 finish the survey within the allowed maximum time. Again, participants were compensated 655 with £1.25 for completing the first part of the study (estimated average completion time 9) 656 minutes, estimated hourly rate of £8.33). In average, participants took 07:37min to 657 complete the first part. 658

Of the additional 50 participants that completed testday 1, 28 subjects finished testday 2. Additional three subjects returned their submission, i.e., decided to leave the study early or withdrew their submission after study completion. One additional participant timed out, i.e., did not finish the survey within the allowed maximum time.

Again, participants were compensated with £1.50 for completing the second part of the study (estimated average completion time 9 minutes, estimated hourly rate of £10). In average, participants took 06:30min to complete the second part of the study.
